Chapter 1

Introduction

Health has played an important role in human history, helping civilization, behind the curtains, to evolve into the society of today[38]. Recently, the healthcare sector has witnessed the development of a wide range of IoT devices and applications[30]. And a new field has been unlocked: Healthcare information technology (HIT).

1.1 Background

Healthcare information technology (HIT) has been defined as “the application of information processing involving both computer hardware and software that deals with the storage, retrieval, sharing, and use of healthcare information, data, and knowledge for communication and decision making[20]” where the oil of it is the Medical Informatics as Morris F Collen defines it: “Medical informatics is the application of computer technology to all fields of medicine-medical care, medical teaching and medical research”; in other words The medical informatics is the foundation for understanding and practice of the up-to-day medicine. Its basic tool is the computer, the subject of studying and the means by which the aspects and achievement in the new knowledge in studying of a man, his health and disease and functioning of the total health activities is performed[28].

Medical informatics as a discipline is still young, in particular when you compare it with other medical disciplines. However, within the past decades, societies in general, and medicine and healthcare in particular, have tremendously changed by the adoption of health information technology. This change has significantly impacted the healthcare field as well[25]. As a result, health information technology improves patient’s safety by reducing medication errors, reducing adverse drug reactions, and improving compliance to

practice guidelines. There should be no doubt that health information technology is an important tool for improving healthcare quality and safety[14].

1.2 Problem & motivation

With the progress of health information technology the healthcare data is increasingly digitized and, like in most other industries, data is growing in Velocity, Volume and Value. According to Statista[7], the amount of global healthcare data is expected to increase dramatically by the year 2020. Early estimates from 2013 suggest that there were about 153 exabytes of healthcare data generated in that year. However, projections indicate that there could be as much as 2,314 exabytes of new data generated in 2020 (Figure 1.1).

Figure 1.1: Total amount of global healthcare data generated in 2013 and a projection for 2020* (in exabytes).

Health Data Management is the practice of making sense of this data and managing it to the benefit of healthcare organizations, practitioners, and ultimately patient well being and health, It enables the integration and analysis of medical data to make patient care more efficient, and extract insights that can improve medical outcomes, while protecting the security and privacy of the data. In the past forty years, medical data began a transition from purely paper-based tracking to digitized information. Even today, many types of medical data have yet to be digitized, or have not yet been integrated into Health Data Management systems. Some of the important challenges facing health data professionals today are[6]:

- ***Fragmented data:*** medical data can be structured data in spreadsheets or databases, images or video files, digital documents, scanned paper documents, or may be stored in specialized formats such as the DICOM format used for MRI scans. Data is widely duplicated, collected multiple times and stored in different versions by healthcare providers, public health organizations, insurance bodies, pharmacies, and patients themselves. There is no one source of truth for information on patient well being.
- ***Changes to data:*** medical data constantly changes as do the names, professions, locations and conditions of patients and physicians. Patients undergo numerous tests and are administered many types of treatment over the years, and the treatments and medications themselves evolve over time. New types of medical treatment, such as telehealth models, create new types of data.
- ***Regulations and compliance:*** medical data is sensitive and must adhere to government regulations, such as the USA Health Insurance Portability and Accountability Act (HIPAA). Data discovery challenges and poor data quality make it much more difficult to perform the required audits and meet regulatory requirements and limits the diversity of data healthcare providers can use for the benefit of patients.

1.3 Purpose & delimitations

The goal of this work is to design a visualization system for medical data in a conventional common language between the different health actors.

We intend to achieve our goal by designing a

1.4 Document structure

This document is presented in n chapters

startig with chapter 1

Chapter 2

Health sector & Data

Healthcare is a multi-dimensional system established with the sole aim for the prevention, diagnosis, and treatment of health-related issues or impairments in humans. There are three components of a healthcare system[21]:

- The health professionals (physicians or nurses): belong to various health sectors like dentistry, medicine, midwifery, nursing, psychology, physiotherapy, and many others.
- Health facilities (clinics, hospitals for delivering medicines and other diagnosis or treatment technologies).
- Financing institution supporting the former two.

Healthcare is required at several levels depending on the urgency of situation:

1. **Primary care:** Professionals serve it as the first point of consultation.
2. **Secondary care:** acute care requiring skilled professionals.
3. **Tertiary care:** advanced medical investigation and treatment.
4. **Quaternary care:** highly uncommon diagnostic or surgical procedures.

At all these levels, the health professionals are responsible for different kind of information such as a patient's medical history (diagnosis and prescriptions related data), medical and clinical data (like data from imaging and laboratory examinations), and other private or personal medical data

Regardless of what form it takes, data has the potential to tell stories, identify cost savings and efficiencies, new connections and opportunities, and enable improved understanding of the past to shape a better future[39].

The term “big data” has become a buzzword in recent years, with its usage frequency having doubled each year in the last few years according to common search engines (Figure 2.1).

Figure 2.1: Cumulative number of publications referring to “big data” indexed by Google Scholar.

Big data is a vague term with a definition that is not universally agreed upon. A definition by Demchenko et al[22] who define Big Data by five V’s: Volume, Velocity, Variety, Veracity, and Value. Volume pertains to vast amounts of data, Velocity applies to the high pace at which new data is generated, Variety pertains to the level of complexity of the data, Veracity measures the genuineness of data, and Value evaluates how good the quality of the data is in reference to the intended results.

If we trace the relationship between the use of the term big data per health research, we can easily infer the growth of medical informatics (Figure 2.2). Big data in health is concerned with meaningful datasets that are too big, too fast, and too complex for healthcare providers to process and interpret with existing tools[17].

Figure 2.2: Cumulative number of publications per health research area referring to “big data,” as indexed in IEEE Xplore, ACM Digital library, PubMed (National Library of Medicine, Bethesda, MD), Web of Science, and Scopus.

There are numerous current areas of research within the field of Health Informatics, including Bioinformatics, Image Informatics (e.g. Neuroinformatic), Clinical Informatics, Public Health Informatics, and also Translational BioInformatics (TBI). Research done in Health Informatics (as in all its subfields) can range from data acquisition, retrieval, storage, analytics employing data mining techniques, and so on.

Data gathered for Health Informatics research does exhibit many of these qualities. Big Volume comes from large amounts of records stored for patients: for example, in some datasets each instance is quite large (e.g. datasets using MRI images or gene microarrays for each patient), while others have a large pool with which to gather data (such as social media data gathered from a population). Big Velocity occurs when new data is coming in at high speeds, which can be seen when trying to monitor real-time events whether that be monitoring a patient’s current condition through medical sensors or attempting to track an epidemic through multitudes of incoming web posts (such as from Twitter). Big Variety pertains to datasets with a large amount of varying types of independent attributes, datasets that are gathered from many sources (e.g. search query data comes from many different age groups that use a search engine), or any dataset that is complex and thus needs to be seen at many levels of data throughout Health Informatics.

Schematically, several health-related activities can be distinguished[27]:

- Pre-admission, admission and administrative discharge activities.
- T2A invoicing or valuation activities.
- Care activities in the accommodation service.
- Activities in operating theaters and technical platforms.
- Laboratory activities.
- Imaging activities.

For each activity, different types of data are generated. In France and most developed countries, the following data is collected and digitally available (in chronological order)[1, 19]:

1. **Administrative data** related to patient movements (identity, dates, places, etc.), demographic (age, sex, place of residence, etc.) and insurance (health coverage, etc.).
2. **Results of biological analyses**, generally taken by nurses and analyzed by professionals or by robots.
3. **Medical data** produced automatically by autonomous medical devices. These devices can be implantable or external.
4. **Data relating to the drugs administered to the patient**, generally by nurses or doctors, possibly as part of a diagnostic or therapeutic procedure.
5. **Data relating to medical devices** implanted in the patient during surgery.
6. **Data relating to medical procedures**, whether diagnostic or therapeutic. These data are generally coded by the producer, sometimes by the machine which produces them.
7. **Comments** in free text, possibly formalized in letters or reports.
8. **Medical diagnoses**, coded a posteriori by the doctors who treated the patient, or by specialized technicians reading the letters[24].

This data can be structured (which can be used directly by an algorithm) or unstructured (they are stored without a predefined format, such as the text of reports or medical letters, and are interpreted by humans). Machines generally produce raw structured information (eg medical biology measurements), while healthcare professionals exchange unstructured information with high interpretative value (eg a diagnosis). Medical records are created by aggregating information from different sources: (Table 2.1) gives an overview of this data[27].

Category	Nature	Structure
Administrative data	Values, Text	Structured
Communications between caregivers (Transmissions and medical observations, medical letters, reports)	Text	Unstructured
Data managed by centralized pharmacies	Values	Structured
Medical biology results	Values, Text	Structured
Data from monitoring devices	Values	Structured
Image Data Images	Images, Text	Unstructured
PMSI data and codes	Codes, Values	Structured

Table 2.1: Origin, nature and structure of medical record data.

2.1 Medical records management

Self-tracking and documenting information about aspects of one’s personal and daily life has a long history. It is an effective method which helps us to learn more about ourselves, rather than depending on our limited memory[15].

The medical record is a multifunctional document that is used to communicate and document critical information about patients’ medical care among health care professionals. Comprehensive medical records are a cornerstone in the quality and efficiency of patient care during the hospitalization and in subsequent follow-up visits, as they can provide a complete and accurate chronology of treatments, patient results and future plans for care[37], it involves many kinds of records, including patient charts, x-rays, images, scans, and even emails. Additionally, it involves making sure all of these items are accessible, safe, and secure. There are multiple electronic records used in the healthcare.

2.1.1 Electronic medical record

Electronic medical record (EMR) systems, defined as "an electronic record of health-related information on an individual that can be created, gathered, managed, and consulted by authorized clinicians and staff within one health care organization," have the potential to provide substantial benefits to physicians, clinic practices, and health care organizations.

It is a digital version of the paper medical record that has been used for years and it will contain the patient's medical and surgical history, allergy information, treatment history, current, and past prescriptions, and other pertinent information that can be used in making future medical decisions[13]. These systems can facilitate workflow and improve the quality of patient care and patient safety[5].

2.1.2 Electronic health record

An Electronic Health Record (EHR) is an electronic version of a patient's medical history, that is maintained by the provider over time, and may include all of the key administrative clinical data relevant to that persons care under a particular provider, including demographics, progress notes, problems, medications, vital signs, past medical history, immunizations, laboratory data and radiology reports. The EHR automates access to information and has the potential to streamline the clinician's workflow. It also has the ability to support other care-related activities directly or indirectly through various interfaces, including evidence-based decision support, quality management, and outcomes reporting.

EHRs are the next step in the continued progress of healthcare that can strengthen the relationship between patients and clinicians. The data, and the timeliness and availability of it, will enable providers to make better decisions and provide better care[4].

2.1.3 The Difference Between EMR & EHR

Both the EMR and EHR contain electronic versions of a patient's medical history. Most of the information in an EMR goes into an EHR.

The EMR can contain medical history, diagnoses, medications, immunizations and dates, allergies, etc. Often, a patient needs to ask for a printed copy of an EMR to share with another medical provider.

The EHR contains similar details as the EMR, but also other relevant data like information from wearable devices, demographics, and insurance information. It can also contain lab data and imaging reports that come

from other offices or practices. Assuming the software is compatible, other offices and practices can access the information within an EHR to help coordinate care and make clinical decisions[8] (Table 2.2) gives an overview of this difference:

EMR (electronic medical record)	EHR (electronic health record)
Medical and clinical data gathered in one provider's office	Medical and clinical data gathered from many providers' offices and hospitals
Narrower view	Broader view
Digital version of a paper chart in one office	Digital version of varied health information
Not designed for sharing	Designed for sharing outside of an individual medical practice
Providers use mainly for diagnosis and treatment	Providers have access to many diagnostic tools to make decisions

Table 2.2: EMR vs. EHR: Similarities and Differences.

2.1.4 Personal health record

Electronic Personal Health Records (ePHRs) are a representation of health records connected to the care of a patient and are managed by the patient[23], unlike EHRs, which are managed by health care providers. ePHRs allow healthcare consumers the luxury of deciding which health information to share with healthcare providers[34]. Ozok et al.[9] defined ePHR systems as patient centric, multi-functional, health management systems developed for managing and storing lifelong personal health information for various purposes from chronic to critical, medical and preventive care[16].

The information in an EHR is keyed in by healthcare providers and is only accessible to healthcare providers. In addition, an EHR might only contain information from a single healthcare provider. On the other hand, an individual will retain control of their own ePHR, which might encompass health information from different sources, such as various healthcare providers, as well as from the patient, as integrated ePHRs have the capability to incorporate data from different sources. Thus, at any one time, there may be various EHRs for one person but only one ePHR[16].

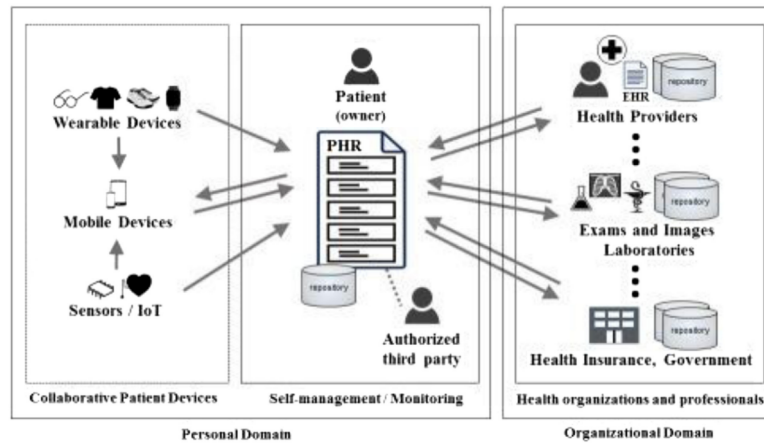

Figure 2.3: Difference between an EHR and ePHR (Token from [16]).

2.2 Security in medical records management

The actual technology of an electronic medical record seems to be falling into place. As the world moves more toward the use of telemedicine to preclude the movement of patients to more advanced facilities, the need for a fully functioning medical record is paramount. One of the important ethical issues in electronic records management involves privacy. Privacy is the “claim of individuals to be left alone, free from surveillance or interference from other individuals, organizations, including state” (Laudon and Laudon 2005:159), privacy deals with the collection and use or misuse of data. Data is constantly being collected and stored on each of us. This data is often distributed over easily accessed networks and without our knowledge or consent[31].

There are a number of security dilemmas in electronic records management. There can be illegal access and use of records, data alteration and destruction (Stair and Reynolds 2006: 583).

Typical cross-organisational e-health applications are[32]:

- sharing of patient records among different healthcare professionals;
- access to distributed EHRs any place and any time;
- on-line teleconsultation, telemonitoring and assistance;
- patient—doctor consultation services;
- patients’ access to their own EHRs.

That is why Electronic health records management attracts significant international interest and sets the scenery for the establishment of a distributed, coalition-based, security policy enhanced records exchange framework among different medical domains. Several European projects have proposed candidate solutions for secure inter-operations between medical domains. In the HARP project, security profiles related to access rights are dynamically downloaded to the client side. The MEDITRAV EUproject attempts to overcome national or linguistic barriers by adopting the solution of a multilingual portable personal record. These approaches, pose mainly their research effort on the security requirements for effective electronic health record management, still they confront mainly to stable infrastructures[18].

Chapter 3

information visualization (infoVis)

Human mind is very visual, following Williams et al., visualization is “a cognitive process performed by humans in forming a mental image of a domain space. In computer and information science it is, more specifically, the visual representation of a domain space using graphics, images, animated sequences, and sound augmentation to present the data, structure, and dynamic behavior of large, complex data sets that represent systems, events, processes, objects, and concepts”[36]. The (Figure 3.1) below presents the Florence Nightingale’s ‘Rose diagram’ published in 1858 showing the reduction in the number of deaths in military hospitals in Scutari arising from the changes she instituted[33] .

Figure 3.1: Rose Diagrame

Data visualization involves presenting data in graphical or pictorial form which makes the information easy to understand. It helps to explain facts and determine courses of action. It will benefit any field of study that requires innovative ways of presenting large, complex information[33].

Traditionally, data visualization has been structured along two main fields: scientific visualization and information visualization. A third, newer field, called visual analytics has emerged in the past several years, as a bridge between and also an extension of the former two fields[35]. In this paper we will focus mainly on the information visualization field.

3.1 Difinition

Information visualization (InfoVis) is the practice of representing data in a meaningful, visual way that users can interpret and easily comprehend, it is a research area that aims to aid users in exploring, understanding, and analyzing data through progressive, iterative visual exploration. With the boom in big data analytics, InfoVis is being widely used in a variety of data analysis applications in different domains, ranging from finance to sports to politics[26].

Information visualizations are often created with an audience in mind and designed to display certain important information that they need to understand. With an idea of how the visualization will be used, using multiple tools (Column chart, Bar graph, Network graph, Stacked bar graph, Histogram, Line chart, Pie chart, Box plot, Bubble chart, Dual-axis chart,...)3.2 that can help users compare different values, show the bigger picture, track trends in the data, and understand different relationships between variables[11]. These tools follow the model of the visualization pipeline.

Figure 3.2: Information visualizations's tools

3.2 Visualization pipeline

A visualization pipeline embodies a dataflow network in which computation is described as a collection of executable modules that are connected in a directed graph representing how data moves between modules. In a basic pipeline (Figure 3.3), there are three types of modules: sources, filters, and sinks. A source module produces data that it makes available through an output. File readers and synthetic data generators are typical source modules. A sink module accepts data through an input and performs an operation with no further result (as far as the pipeline is concerned). Typical sinks are file writers and rendering modules that provide images to a user interface. A filter module has at least one input from which it transforms data and provides results through at least one output[29].

Figure 3.3: A simple visualization pipeline.

As science progresses, this model has been detailed, Figure 3.4 provides an overview of the infoVis pipeline. It has five main modules: Data Analysis, Filtering, Mapping, Rendering, Image data, explained as follows:

Figure 3.4: A simple visualization pipeline.

1. **Raw data:** First, we have to import the data. This implies finding a representation of the original information we want to investigate in terms of a data set. Practically, importing data means choosing a specific dataset implementation and converting the original information to the representation implied by the chosen dataset in order to turn this data into information using Data analysis.

2. **Data Analysis:** Is the process of bringing order and structure to collected data. It turns data into information teams can use. Analysis is done using systematic methods to look for trends, groupings, or other relationships between different types of data[3], following this process:

- **Data Requirements Specification:** The data required for analysis is based on a question or an experiment. Based on the requirements of those directing the analysis, the data necessary as inputs to the analysis is identified (e.g., Population of people). Specific variables regarding a population (e.g., Age and Income) may be specified and obtained. Data may be numerical or categorical[2].
- **Data Collection:** Guided by the requirements identified, Data can be collected through several sources, including online sources, computers, personnel, and sources from the community.
- **Data processing:** The data that is collected must be processed or organized for analysis. For instance, these may involve placing data into rows and columns in a table format (known as structured data) for further analysis, often through the use of spreadsheet or statistical software[2].
- **Data Cleaning:** The processed and organized data may be incomplete, contain duplicates, or contain errors. Data Cleaning is the process of preventing and correcting these errors[2].
- **Perform data analysis:** One of the last steps in the data analysis process is analyzing and manipulating the data. This can be done in a variety of ways depending on the cleaned data nature[12].

The data analysis step produces the prepared data.

3. **Filtering:** Data filtering is the process of choosing a smaller part of your data set and using that subset for viewing or analysis[10], this portion of data called focus data.
4. **Mapping:** Focus data are mapped to geometric primitives (e.g., points, lines) and their attributes (e.g., color, position, size); most critical step for achieving expressiveness and effectiveness.
5. **Rendering:** The rendering operation is the final step of the visualization process, rendering takes the geometric data created by the mapping operation and transforms it to an image data.
